\textbf{Abstract.} We report the recent progress of our proposed renewable energy cycle based on magnesium and solar-energy-pumped laser. The solar energy is used to recycle the used magnesium, MgO, to recover new magnesium and magnesium is used as fuel-cell battery. The batteries for the cell phone, automobiles and others have already been developed and demonstrated. The magnesium of 24kg is proven to drive a car for 500km without charging.

\textbf{Key words}
Solar Energy, Magnesium, Recycle, Battery, Energy Carrier.

1. Introduction

Nowadays typhoon is growing its size and there frequently occurred anomalous atmospheric phenomena. No one can deny that it is a consequence of change of terrestrial environment owing to CO\textsubscript{2} emission. The difference of vaporization between tropical area and northern area leads to the difference of salinity which drives global ocean circulation. There is a movie in which the global warming reduces such salinity difference and finally stops the global circulation and entire American continents are frozen. This is not a science fiction but has solid scientific basis. Some body, who insists there is no global warming but is cooling, may not understand the real picture of Earth which stands with delicate balance.

We are obliged to pass over this Earth to our descendants as it is. We created the system to waste fossil fuels that were formed during millions or billions of years, in only 200 years. We must show how to recover the Earth as soon as possible.

The Earth provided us huge resources of magnesium in the ocean and huge resources should be environment-friendly because we were born from ocean. We show here that magnesium is the best candidate for renewable energy sources [1].

2. How to Store the Solar Energy?

There exist several candidates for storing the solar energy or other energy. However, it is important to note that three major points must be cleared. (1) It must be transportable, (2) The employed materials must be abundant. (3) All the processes should not harm the environment.

Since the place, where the solar energy is rich and stably available, is limited to the place far from the area where the electricity is fully needed, it must be transported easily. Using the electrical cable for a long distance power supply crossing several countries is not practical because of huge construction cost and national security.

Considering that 10 billion fossil fuels are consumed in every year, huge amount of materials should be required to replace such energy.

Hydrogen might be one possibility, however energy density per volume is very small compared with gasoline even in the liquid form. For example, the density of liquid hydrogen is 70.8kg/m\textsuperscript{3} at the temperature of 20K and reaction energy of hydrogen molecule is 120MJ/kg and 8.5GJ/m\textsuperscript{3} which should decrease if the container and cooling system down to 20K are included. In contrast, reaction energy of gasoline is 50MJ/kg and 39GJ/m\textsuperscript{3}, and that of magnesium is 25.2MJ/kg and 43.8GJ/m\textsuperscript{3}.

Liquid methanol (CH\textsubscript{3}OH) as hydrogen carrier has the density of 793kg/m\textsuperscript{3} and includes hydrogen of 99kg/m\textsuperscript{3} that corresponds to 11.9GJ/m\textsuperscript{3}. However, it emits CO\textsubscript{2} during the process and reaction speed is too slow.
We proposed to use magnesium as storing material [1] because it is abundant and resources in the ocean amounts up to 1.8 quadrillion tons. The reaction product is MgO or Mg(OH)$_2$ which are harmless and in solid state that can be easily collected. Only problem is how to produce and recycle it. We proposed to use lasers to recycle magnesium.

Magnesium compounds can be extracted either from the ocean or mine in solid form. These compounds are refined by using lasers as shown in Fig.1. The lasers are directly solar-energy-pumped laser ([2]-[7]) or semiconductor lasers pumped by electricity from various sources. Refined pure magnesium is used for mobile phone, automobile, and power reactor.

3. Magnesium Fuel-Cell Battery

A. Film-Type Battery

We proposed a new battery using magnesium. The battery is composed of reaction chamber and magnesium as shown in Fig.2. The magnesium is used in the form of thin film and is stored in the cartridge. After thin film is consumed in the reaction chamber, reaction products Mg(OH)$_2$ and/or MgO are moved away from the chamber and new film automatically enters into the chamber by winding the film using some mechanism like spring or small motor. By using such thin magnesium film, we demonstrated the battery capacity of 1300 Ah/kg which is 9 times larger than 150Ah/kg of Lithium-Ion battery.

Conventional magnesium air battery uses thick plate of magnesium but after a thin surface layer is oxidized, rest of the part remains not reacted. This was the origin of low efficiency. Using thin layer of magnesium, however, almost all of the magnesium are fully used.

There are alternative methods to increase the efficiency using some chemical reaction to remove oxidized layer but without using film. However such reaction speed is always very slow compared with pure magnesium reaction. Therefore addition of slow reaction makes the output electric current very small. For example, only 0.5A is achieved with 5cm x 5cm magnesium in such thick plate scheme, while 10A is achieved with the same area of thin film by our proposed new film method.

In addition, using chemical reaction to remove oxidized layer leads to serious difficulties such that oxidized magnesium is mixed with electrolyte leading to degradation of conductivity. Therefore frequent replacement of electrolyte is required. In our case, oxidized layer can be held and moved away from the reaction chamber by some method and is not mixed with electrolyte. Since we only need the water that is responsible for reaction, the amount of electrolyte is similar to the amount of magnesium.

B. Battery for Cell Phone

Since fuel of magnesium is outside of reaction chamber in our method, the size of whole battery is independent of battery capacity and hence any capacity can be realized by increasing the amount of magnesium. This is the typical feature of fuel-cell battery. Thus the battery

Figure 1 Magnesium recycling system.

Figure 2 Magnesium fuel-cell battery.

Figure 3 Conventional magnesium air battery.

Figure 4 Magnesium fuel-cell battery is used as a cover and drives cell phone for a month without charging.
becomes very compact. Let us consider a battery for cell phone. The capacity of conventional cell phone is 1500-2000 mAh. Since we already achieved 1300mAh/g, 30g of magnesium can drive cell phone during one month without charging. The size of 30 g magnesium is a cylinder of 5mm-high and 6.6cm-diameter, and it can be installed inside cell phone.

C. Battery for Automobile

Figure 5  Magnesium fuel-cell battery for automobile whose total weight is 200kg. Collaboration with Fujikura Rubber Ltd.

For larger size, we already developed a cell that can deliver more than 20A and 10W whose cell area is 170mm x 340mm and we shall develop a new cell of 300mm x 600mm that can deliver 60A and 30W. By accumulating 100 of these cells, 3kW model (peak power) will be finalized in 2014 with the size of 300mm x 600mm x 600mm. This size should be further reduced by improving battery efficiency and packing method. By this battery, we can drive an electric golf cart. 3 modules of this battery can drive a car for one person.

C. Air Battery vs Magnesium Fuel-Cell Battery

In the above discussion we only mentioned peak power. This is very interesting point of our battery. Conventional secondary battery needs to be charged and hence the stored energy like kWh is the key issue for comparison of its performance. The same discussion also applies to conventional "Air Battery" that uses thick plate of Mg.

In our film-type battery, which we call here "Magnesium Fuel-Cell Battery", the main battery system, reaction chamber, is separated from magnesium fuel in the form of film cartridge. This system is easily understood by comparing it with gasoline engine which has a combustion chamber and gasoline is stored in a tank. Our reaction chamber corresponds to the reciprocal engine and Mg fuel corresponds to gasoline. Therefore any distance mileage can be reached by increasing the amount of Mg fuel. This means the performance of fuel-cell battery is determined from its peak power like kW or PS and kWh does not depend on the reaction chamber but on fuel amount. Thus most prominent feature of our battery that distinguishes it from other Mg air batteries is that fuel part is separated from reaction part.

4. Magnesium Recycling by Lasers

Reaction product in magnesium battery is refined back to pure magnesium by lasers. Using 1kW CO2 laser, we already succeeded in producing 15mg/kJ [9] and 20mg/kJ with 4kW semiconductor laser. This means 50kJ is used to get 1g of magnesium. Since magnesium of 1g releases the energy of 25.2kJ, the above efficiency of magnesium recovery is 50%. Currently we have 8kW semiconductor laser which can produce 5 tons of magnesium per year. Since magnesium battery reached 60% of theoretical limit 7kWh/kg in laboratory experiment, magnesium of 24kg generate 100kWh sufficient for 500 km mileage of medium-sized car. Therefore 8kW laser can support 208 cars x 500km mileage in one year

8 kW laser that can provide 5 tons of magnesium/year can support the battery for 13,000 cell phones in one year. If 3 billion people use magnesium battery for cell phones, we need to produce magnesium of 1 million tons every year. Since current magnesium production is 0.6 million tons/year, we need to establish magnesium production plants before selling cell phone battery.

For commercial plant, we can start with the combination of wind power generator, geothermal power plant, hydraulic power plant and semi-conductor lasers. Solar pumped laser should come later after the output reaches 400W because it is cheap and directly uses solar energy. The latest maximum output from solar pumped laser is 120W and 400 W is within a reach as shown in the next section.

Figure 6  After laser illumination, magnesium is separated from MgO and evaporated magnesium reaches film and is coated on it.

There is another advantage in using laser. As shown in Fig.6, when high intensity laser illuminates MgO, MgO is disintegrated into magnesium and oxygen, which are ablated with high speed. If we put a thin substrate film, it is coated with the magnesium of more than 10 micron thickness. If the substrate is gradually moved during ablation, roll film of magnesium is automatically produced. Thus magnesium refinement and fuel production can be simultaneously performed.
5. Solar-Energy-Pumped Laser

A. Primary Solar Concentrator

Most of studies[2]-[6]) on solar-pumped laser employed traditional concentrators such as a parabolic mirror, heliostat, and Fresnel lens as the primary concentrator. Among them, a high reflectivity mirror system provides a higher focusing efficiency without chromatic dispersion, while a Fresnel lens is more economical [1].

![Fresnel lens](image1)

Figure 7 Primary solar concentrator that uses Fresnel lens and pumping cavity made of aluminum.

In this study, a 2×2-m Fresnel lens with 2-m focal length was designed for the primary concentrator. As shown in Fig. 7, it is mounted on an automatic solar tracker to follow the sun’s movement. The Fresnel lens is made of Poly methyl methacrylate (PMMA), which is transparent at visible and near infrared (IR) wavelengths, and blocks ultraviolet (UV) solar radiation below about 390 nm and IR of longer wavelengths than 2200 nm. The measured full width at half maximum (FWHM) of solar spot at focal point of the Fresnel lens is 20.4 mm, while the ideal focused sum image without chromatic dispersion should be 18.6 mm [7]

Focusing efficiency of the Fresnel lens could reach 80% by our ray tracing simulation. Unfortunately, however, the measured value is only 50% because of some bubbles and scarring on its surface created in the manufacturing process. In fact, the higher efficiency has been realized with less than 1 m-diameter Fresnel lenses ([1],[10]).

![Pumping chamber](image2)

B. Secondary Concentrator

The laser cavity, which we call the second concentrator, is located at the focal zone of the Fresnel lens. Φ6×100- мм Nd:YAG rod is employed in order to minimize the thermal effect.

The secondary concentrator is a conical mirror as shown in Fig.7 that realizes the hybrid-pumping scheme. It is used to confine the collected solar power by multi reflections, and focus it into laser medium. In experiments, the conical concentrators are made of aluminum. The inner walls are hand-polished or bonded with a protected silver-coated aluminum foil whose reflectivity measured at 632 nm wavelength of them is about 70% or 90%, respectively. However, the aluminum foil will easily be damaged under intense solar radiation condition, if there is no cooling treatment.

In order to improve the efficiency, the liquid light-guide lens (LLGL), that has the structure of a cylinder of coolant sheathing the laser rod and has the additional focusing effect provided by the difference of refraction index between the air and coolant, was adopted [8]. The LLGL, however, must adopt hand-polished cavity because the inner wall of cavity cannot be effectively cooled at present.

The solar input aperture Φᵢ of the second concentrators must be large enough to compensate the chromatic dispersion and the corner effect of the square Fresnel lens. Although the solar radiation at ground has a spectrum from 280 to 4000 nm, a Nd:YAG medium can converted only the spectrum below 870 nm into 1064nm laser wavelength due to its four level laser system. The three-dimensional ray-tracing calculation shows that for Φᵢ = 80 mm input diameter, the second concentrator can receive about 96% of the collected solar power which is valid for lasing.

Figure 8 shows the experimental results of laser output for various incident solar power for the LLGL enhanced laser cavity.

![Graph](image3)

Figure 8. Calculated (lines) and experimental (symbols) results of output laser power for Φ6×100-mm Nd:YAG rod which was pumped by 70% reflectivity hybrid concentrator and 14-mm diameter LLGL. R is the reflectivity of output coupler. The thin and thick line are calculated results of R=90% and R=85% respectively.
6. Conclusion

We proposed the renewable energy cycle to use the magnesium as container of solar energy. The magnesium fuel-cell battery is demonstrated by small car and cell phone. By this battery, we can use the smartphone for a month without charging. The magnesium fuel-cell battery is analogous to gasoline engine, that is, reaction chamber and fuel are separated, and hence by increasing fuel it can drive a car for a long distance.

Recycling of reacted magnesium can be performed by semiconductor laser and solar-energy-pumped laser.
